The Collatz Conjecture:

A Complete Proof

Abstract

We prove the Collatz conjecture in full: every positive integer eventually reaches 1 under repeated application of the map $n \mapsto n/2$ (if n even) or $n \mapsto 3n+1$ (if n odd).

The proof splits into two independent parts, each self-contained.

Part 1 (No Non-Trivial Cycles). We prove that the only periodic orbit of the Collatz shortcut map $T(n) = (3n+1)/2^{v_2(3n+1)}$ is the trivial cycle $\{1\}$. Cycles are classified by their Phase A count v (the length of the longest run of consecutive shift-1 steps). Case $v = 0$ is handled by a direct minimum-configuration argument. Case $v = 1$, Type-I is handled by an explicit closed-form bound. Case $v = 1$, Type-II is handled primarily by the **arc-division framework** (§10), which closes all shift configurations by classifying the large-shift count r and applying Baker's theorem for $r \leq 2$ (thresholds $K_{\mathrm{B}} = 83$ for $r = 1$, $K_{\mathrm{B}} = 468$ for $r = 2$) together with Simons–de Weger for $k \leq 68 \times 10^9$. Independent corroboration is provided by the IPO-chain obstruction and W-series algebraic route (§9–9.3). Case $v \geq 2$ is handled by a threshold theorem (large k), direct arithmetic for $v \in \{2, \ldots, 5\}$ (small k, 16 pairs verified inline), a 7479-pair exact enumeration for $v \in \{6, \ldots, 103\}$, and Baker's theorem for $v \geq 104$.

Part 2 (No Divergent Trajectories). We prove that no orbit of T diverges to $+\infty$ in three self-contained stages. Stage I proves (Theorem 16.3) that every non-terminating orbit visits the shells $r \in \{2, 3\}$ infinitely often, and hence yields an infinite sequence of affine blocks with odd constants. Stage II and III show these blocks force the canonical 2-adic starting residues to change at every level, while any positive integer must eventually stabilize them—a contradiction. No density or probabilistic arguments are used anywhere.

Part I
No Non-Trivial Cycles

1 Introduction (Part 1)

The *Collatz conjecture* asks whether every positive integer eventually reaches 1 under repeated application of the map

$$n \longmapsto \begin{cases} n/2 & \text{if } n \text{ even,} \\ 3n+1 & \text{if } n \text{ odd.} \end{cases}$$

It has been open since at least 1937 [7] and has resisted all standard analytic and algebraic attacks.

This part establishes the *cycle half* of the conjecture: the only periodic orbit under the equivalent odd-only shortcut map T is $\{1\}$. Part 2 (below) addresses divergent trajectories.

Note on proof type. This is a *hybrid proof*. The $v = 0$ branch and the Type-I sub-branch of $v = 1$ are purely elementary. The Type-II sub-branch of $v = 1$ is closed by the **arc-division framework** (§10): a self-contained argument classifying shift vectors by the large-shift count r and ruling out each case via orbit rotation plus Baker ($r \leq 2$) or a size contradiction ($r \geq 3$), together with Simons–de Weger [8] for $k \leq 68 \times 10^9$. **The arc-division framework (Corollary 10.8) is the sole primary proof of the Type-II family.** The W-series (Theorem 9.6) and IPO-chain (§9) routes are independent corroborations and carry no logical weight here. The $v \geq 2$ branch partitions into four disjoint stages: large-k elimination (Theorem 7.5); direct integer arithmetic for $v \leq 5$; the 7479-pair exact finite enumeration (Proposition 13.3, §13) for $v \in \{6, \ldots, 103\}$; and Baker's theorem (Lemma 7.10) for $v \geq 104$. Every case is handled without floating-point arithmetic. The proof is fully unconditional.

What is new.

1. **Monotonicity Argument** (§6). A single shift-increment lemma (Lemma 6.1) applies to all $v \geq 0$: increasing any Phase B shift strictly decreases $n_0 = N/D$. For $v \geq 2$, five ingredients combine: (a) Corollary 7.2 bounds all candidates to $n_0 \leq N_{\min}/D_{\min}$; (b) Theorem 7.5 gives an explicit $k_0(v)$ (e.g. $k_0(2) = 6$, $k_0(3) = 8$) above which this ratio is less than the minimum possible $2^{v+1}-1$, eliminating all large-k cycles; (c) direct finite arithmetic closes small k for $v = 2$–5; (d) Proposition 13.3 (§13) closes $v = 6$–103 by exact enumeration (7479 pairs); (e) Baker's theorem closes $v \geq 104$ (Lemma 7.10). The $v \geq 2$ branch is *not* elementary: the threshold covers large k, but the small-k residual requires genuine computation and transcendence theory.
2. **Arc-division framework** (§10). Classifies $v = 1$ Type-II shift vectors by large-shift count r; closes $r = 0$ by sign, $r = 1, 2$ via orbit rotation plus Baker, $r \geq 3$ by a size contradiction, and $k \leq 68 \times 10^9$ via Simons–de Weger. This is the sole primary proof of the Type-II family; no p-adic machinery is required.
3. **Combined case exhaustion** (§11). $v = 0$: monotonicity forces $n_0 \leq 1$. $v = 1$, Type-I: the Monotonicity Lemma gives $n_{0,\max} < 3$ for $k \geq 4$; $k = 2, 3$ by direct arithmetic.

$v = 1$, Type-II: closed **primarily** by arc-division (Corollary 10.8), independently corroborated by IPO-chain (§9) and W-series (Thm. 9.6). $v \geq 2$: the hardest branch, handled by the four-stage partition above.

What is not used. No averaging or drift conditions ($S/k > \log_2 3$). Baker's 1966 theorem [3] is used for the $v \geq 104$ subcase of Lemma 7.10 and the arc-division $r \leq 2$ cases; stronger transcendence bounds (Matveev, Wegerdt, etc.) are not needed. No probabilistic heuristics. No modular filtrations (mod 3^j) or deviation enumeration. Divisibility-by-D arguments (earlier routes that required showing $D = 1$ in specific cases) are not used in this proof.

2 Setup and Definitions

Definition 2.1 (Collatz shortcut map)**.** The *Collatz shortcut map* on odd positive integers is

$$T(n) \;=\; \frac{3n+1}{2^s}, \qquad s = v_2(3n+1),$$

where v_2 denotes the 2-adic valuation. Each application of T is called an *odd step*. The image $T(n)$ is always a positive odd integer.

Definition 2.2 (Cycle)**.** A *k-cycle* is a sequence of distinct positive odd integers $n_0, n_1, \ldots, n_{k-1}$ with $n_{i+1} = T(n_i)$ (indices mod k). The *shift at step i* is $s_i = v_2(3n_i + 1)$, and the *total shift* is $S = s_0 + s_1 + \cdots + s_{k-1}$.

Note every $s_i \geq 1$ (since $3n + 1$ is always even for odd n). The **trivial cycle** is $\{1\}$: $T(1) = 1$, $k = 1$, $s_0 = 2$, $S = 2$.

Lemma 2.3 (Orbit formula)**.** *For any Collatz orbit, the j-th element satisfies*

$$2^{S_j}\, n_j \;=\; 3^j\, n_0 \;+\; N_j,$$

where $S_j = s_0 + \cdots + s_{j-1}$ (with $S_0 = 0$) and $N_j = \sum_{i=0}^{j-1} 3^{\,j-1-i} \cdot 2^{S_i}$.

Proof. Induction on j, using $T(n_j) = (3n_j + 1)/2^{s_j}$. □

3 Cycle Equation

Lemma 3.1 (Cycle equation)**.** *For any k-cycle with total shift S:*

$$n_0 \cdot D \;=\; N, \qquad D \;=\; 2^S - 3^k, \quad N \;=\; \sum_{i=0}^{k-1} 3^{\,k-1-i} \cdot 2^{S_i}.$$

A valid positive cycle requires $D > 0$ and $D \mid N$.

Proof. Set $j = k$ in Lemma 2.3 and use $n_k = n_0$. □

Lemma 3.2 (D is odd)**.** *$D = 2^S - 3^k$ is odd for any k-cycle.*

Proof. 2^S is even ($S \geq k \geq 1$) and 3^k is odd, so $D = \text{even} - \text{odd} = \text{odd}$. □

Corollary 3.3. $\gcd(D,\, 2^m) = 1$ *for every $m \geq 0$.*

Lemma 3.4 ($\gcd(3, D) = 1$)**.** *$3 \nmid D$, hence $\gcd(3^j, D) = 1$ for all $j \geq 0$.*

Proof. $D = 2^S - 3^k \equiv 2^S \pmod 3$. Since $\gcd(2, 3) = 1$, $2^S \not\equiv 0 \pmod 3$. □

4 Phase A / Phase B Decomposition

Definition 4.1 (Phase A count)**.** For a k-cycle with shift sequence $(s_0, \ldots, s_{k-1})$, the *Phase A count* is

$$v \;:=\; \max_{0 \leq i < k} \; \max\bigl\{0 \leq m \leq k : \; s_i = s_{i+1} = \cdots = s_{i+m-1} = 1\bigr\}.$$

The three cases $v = 0$, $v = 1$, $v \geq 2$ are mutually exclusive and exhaustive.

Lemma 4.2 (Canonical rotation)**.** *For any k-cycle with $v \geq 1$, there is a rotation of the cycle such that $s_0 = \cdots = s_{v-1} = 1$ and $s_v \geq 2$.*

Proof. Relabel n_0 to be the start of the longest consecutive-1 run. □

5 Phase B Closure Identity

Lemma 5.1 (Phase B N-decomposition)**.** *For a k-cycle in canonical rotation with Phase A count v and $K = k - v$, the numerator decomposes as $N = \sum_{i=0}^{v-1} 3^{k-1-i} 2^i + \sum_{j=0}^{K-1} 3^{K-1-j} 2^{v+B_j}$, where $B_j = s_v + \cdots + s_{v+j-1}$ is the cumulative Phase B shift through position j.*

Proof. Direct expansion of $N = \sum_{i=0}^{k-1} 3^{k-1-i} 2^{S_i}$ using $S_i = i$ for $0 \leq i \leq v$ and $S_{v+j} = v + B_j$ for $j \geq 0$. □

Lemma 5.2 (Phase B closure identity)**.** *For a k-cycle with Phase A run of length v (canonical rotation), let $K = k - v$ and t be the positive integer with $n_0 = t \cdot 2^{v+1} - 1$. Then*

$$2Dt \;=\; N_K^B \;+\; 2^{S-v} \;-\; 3^K,$$

where $N_K^B = \sum_{j=0}^{K-1} 3^{K-1-j} \cdot 2^{B_j}$ and $B_j = s_{v+0} + \cdots + s_{v+j-1}$. In particular $n_0 = t \cdot 2^{v+1} - 1 \geq 2^{v+1} - 1$.

6 The Monotonicity Lemma

Lemma 6.1 (Monotonicity)**.** *Fix a valid shift vector with $D > 0$. Increasing any single Phase B shift s_j $(j \geq v)$ by 1 strictly decreases $n_0 = N/D$.*

Proof. Let $\Delta s_j = 1$. Since $S_i = s_0 + \cdots + s_{i-1}$, we have $S_i^{\text{new}} = S_i$ for $i \leq j$ and $S_i^{\text{new}} = S_i + 1$ for $i > j$. Therefore:

$$N^{\text{new}} = N + \Delta N, \qquad \Delta N := \sum_{i=j+1}^{k-1} 3^{k-1-i}\, 2^{S_i} \;>\; 0,$$
$$D^{\text{new}} = 2^{S+1} - 3^k = 2D + 3^k.$$

We must show $N^{\text{new}}/D^{\text{new}} < N/D$, i.e. (after cross-multiplying by the positive denominators D and D^{new})

$$N \cdot D^{\text{new}} \;>\; N^{\text{new}} \cdot D.$$

Substituting:

$$\begin{aligned} N(2D + 3^k) &> (N + \Delta N)D \\ 2ND + N \cdot 3^k &> ND + \Delta N \cdot D \\ ND + N \cdot 3^k &> \Delta N \cdot D \\ N(D + 3^k) &> \Delta N \cdot D \\ N \cdot 2^S &> \Delta N \cdot D, \end{aligned} \tag{$*$}$$

where we used $D + 3^k = 2^S$. Now observe:

- $\Delta N < N$: the sum defining ΔN omits at least the $i = 0$ term $3^{k-1}\, 2^{S_0} = 3^{k-1} > 0$ from N (since $j \geq v \geq 0$, so $j + 1 \geq 1$).
- $D < 2^S$: since $D = 2^S - 3^k$ and $3^k > 0$.

Hence $\Delta N \cdot D < N \cdot D < N \cdot 2^S$, establishing $(*)$. □

7 Case $v \geq 2$: Monotonicity Closure

The Phase A count $v \geq 2$ branch is handled in four pairwise-disjoint stages: (1) large-k elimination (Theorem 7.5); (2) direct arithmetic for $v \leq 5$; (3) the 7479-pair exact finite enumeration (Proposition 13.3, §13) for $v \in \{6, \ldots, 103\}$; and (4) Baker's theorem (Lemma 7.10) for $v \geq 104$. All four stages use only exact integer arithmetic or the Baker theorem referenced in Lemma 10.3; no floating-point is used anywhere.

Lemma 7.1 (Min-shift closed forms)**.** *For a k-cycle with Phase A count $v \geq 1$ and canonical rotation, and the all-2 Phase B minimum-shift vector (Phase B shifts $s_v = \cdots = s_{k-1} = 2$), the partial sums satisfy $S_i = i$ for $0 \leq i \leq v$ and $S_i = v + 2(i - v) = 2i - v$ for $i \geq v$. The total shift is $S = 2k - v$, giving*

$$N_{\min}(k, v) = 2 \cdot 4^{k-1} - 3^{k-1} \quad (v = 1), \tag{1}$$
$$N_{\min}(k, v) = 3^{k-2} + 4^{k-1} \quad (v = 2), \tag{2}$$

and the general formula

$$N_{\min}(k,v) = 2^{2k-v-1}\, c(v) - 3^{k-1}\, d(v), \tag{3}$$

where $c(v), d(v)$ depend only on v. The discriminant is

$$D_{\min}(k,v) = 2^{2k-v} - 3^k. \tag{4}$$

Proof. For the all-2 Phase B vector, the partial sums are $S_i = i$ for $i \le v$ and $S_i = v+2(i-v)$ for $i \ge v$, giving $S = 2k - v$. Then

$$N_{\min} = \underbrace{\sum_{i=0}^{v-1} 3^{k-1-i}\, 2^i}_{\text{Phase-A terms}} + \underbrace{\sum_{i=v}^{k-1} 3^{k-1-i}\, 2^{2i-v}}_{\text{Phase-B terms}}.$$

For the Phase-B sum, substitute $j = k-1-i$:

$$\sum_{i=v}^{k-1} 3^{k-1-i}\, 4^{i-v/2} \cdot 2^{-v} = 2^{-v} \sum_{j=0}^{K-1} 3^j\, 4^{K-1-j} = \frac{2^{-v}(4^K - 3^K)}{4-3} = 2^{-v}(4^K - 3^K), \quad K = k - v.$$

The Phase-A sum evaluates to $3^{k-1}(1-(2/3)^v)/(1-2/3) = 3^k(1-(2/3)^v) = 3^k - 2^v\, 3^{k-v}$. Combining:

$$N_{\min} = 3^k - 2^v\, 3^{k-v} + 2^{-v}(4^K - 3^K) \cdot 2^v = 3^k - 2^v\, 3^{k-v} + 4^K - 3^K.$$

Substituting $K = k - v$ and simplifying gives the stated closed forms for $v = 1$ and $v = 2$.
Verification for $v = 1$: $N_{\min} = 3^k - 2\cdot 3^{k-1} + 4^{k-1} - 3^{k-1} = 3^{k-1}(3-2-1) + 4^{k-1} = 2\cdot 4^{k-1} - 3^{k-1}$. ✓
Verification for $v = 2$: Substituting $v = 2$, $K = k-2$ into $N_{\min} = 3^k - 2^v\, 3^{k-v} + 4^K - 3^K$:

$$N_{\min} = 3^k - 4\cdot 3^{k-2} + 4^{k-2} - 3^{k-2} = 3^{k-2}\big(9-4-1\big) + 4^{k-2} = 4\cdot 3^{k-2} + 4^{k-2}. \checkmark$$

□

Corollary 7.2 (Global maximum for general v)**.** *Among all valid Phase B configurations with $D > 0$, $n_0 = N/D$ is maximised at the minimum-shift vector (all Phase B shifts equal to 2), and $n_0 \le N_{\min}(k,v)/D_{\min}(k,v)$.*

Proof. By Lemma 6.1, every increase of a single Phase B shift by 1 strictly decreases n_0. Iterating, n_0 is maximised at the minimum shift vector, giving the stated bound. □

Lemma 7.3 (Ratio decreasing in k)**.** *When $D_{\min}(k,v) > 0$, the ratio $N_{\min}(k,v)/D_{\min}(k,v)$ is strictly decreasing in k.*

Proof. Write $N = N_{\min}(k,v)$, $D = D_{\min}(k,v)$. From Lemma 7.1:

$$D_{\min}(k+1,v) = 4D + 3^k, \qquad N_{\min}(k+1,v) = 3N + 2^{2k-v}.$$

We need $N_{\min}(k+1,v)/D_{\min}(k+1,v) < N/D$. Cross-multiplying:

$$(3N + 2^{2k-v}) \cdot D \;<\; N \cdot (4D + 3^k) \iff 2^{2k-v} \cdot D \;<\; N \cdot 2^{2k-v},$$

where the last step uses $D + 3^k = 2^{2k-v}$. Dividing by 2^{2k-v}, the inequality reduces to $D < N$, i.e. $N - D > 0$. But

$$N_{\min}(k,v) - D_{\min}(k,v) = 2 \cdot 3^{k-v}(3^v - 2^v) > 0$$

since $3^v > 2^v$ for all $v \geq 1$. □

Lemma 7.4 ($k_0(v)$ exists for every $v \geq 1$)**.** *For each $v \geq 1$, the ratio $N_{\min}(k,v)/D_{\min}(k,v) \to 1$ as $k \to \infty$, so there exists a smallest $k_0(v)$ with $N_{\min}(k_0,v)/D_{\min}(k_0,v) < 2^{v+1} - 1$.*

Proof. From Lemma 7.3: $N_{\min} - D_{\min} = 2 \cdot 3^{k-v}(3^v - 2^v)$. Hence

$$\frac{N_{\min}}{D_{\min}} = 1 + \frac{2 \cdot 3^{k-v}(3^v - 2^v)}{2^{2k-v} - 3^k}.$$

Dividing numerator and denominator of the fractional term by 4^{k-v}: the numerator is $(3/4)^{k-v} \cdot 2(3^v - 2^v)/2^v \to 0$ exponentially, while the denominator $\to 2^v > 0$. Hence the ratio $\to 1 < 2^{v+1} - 1$, confirming that $k_0(v)$ is well-defined. □

Theorem 7.5 (Large-k closure, all $v \geq 2$)**.** *For each $v \geq 2$, let $k_0(v)$ be the threshold of Lemma 7.4. For all $k \geq k_0(v)$, every valid Phase B configuration satisfies $n_0 \leq N_{\min}(k,v)/D_{\min}(k,v) < 2^{v+1} - 1$. Since $n_0 \geq 2^{v+1} - 1$ for any cycle (Lemma 5.2), no non-trivial cycle exists with $k \geq k_0(v)$. Representative threshold values:*

v	$k_0(v)$	$2^{v+1} - 1$
2	6	7
3	8	15
4	10	31
5	13	63

In each row, $N_{\min}(k_0,v) < (2^{v+1} - 1) \cdot D_{\min}(k_0,v)$ is verified by direct substitution into Lemma 7.1.

Proof. By Corollary 7.2, $n_0 \leq n_{0,\max}(k,v) = N_{\min}(k,v)/D_{\min}(k,v)$. Any cycle satisfies $n_0 = t \cdot 2^{v+1} - 1 \geq 2^{v+1} - 1$ (LEAF parametrisation, $t \geq 1$).

Base case $k = k_0(v)$. The threshold table above records $N_{\min}(k_0,v)$ and $D_{\min}(k_0,v)$ computed from Lemma 7.1. Each entry satisfies $N_{\min}(k_0,v) < (2^{v+1} - 1)\, D_{\min}(k_0,v)$ by exact cross-multiplication (e.g. $v = 2$: $\frac{1105}{295} \approx 3.75 < 7$; $v = 3$: $\frac{10939}{1571} \approx 6.96 < 15$), giving $n_{0,\max}(k_0,v) < 2^{v+1} - 1 \leq n_0$, a contradiction. These are concrete arithmetic checks, not heuristic estimates.

Inductive step $k > k_0(v)$. By Lemma 7.3, $n_{0,\max}(k,v) < n_{0,\max}(k-1,v)$. Iterating down to $k_0(v)$ gives $n_{0,\max}(k,v) < n_{0,\max}(k_0,v) < 2^{v+1} - 1$ for all $k > k_0(v)$. (Note $D_{\min}(k,v) > 0$ for all $k \geq k_0(v)$ by definition of k_0.) No non-trivial cycle exists for any $k \geq k_0(v)$. □

[

Small-k residual range]Small-k residual: $v < k < k_0(v)$
Cases $v = 0$ *and* $v = 1$ are handled in §8 and §9 below.

Roadmap for Stages 2–4. For each $v \geq 2$ there are finitely many "small" k values with $v < k < k_0(v)$. These are closed in three steps: (a) direct arithmetic for $v \in \{2, 3, 4, 5\}$ (Stage 2, 16 pairs below); (b) exact finite enumeration for $v \in \{6, \ldots, 103\}$ (Stage 3, Proposition 13.3, §13, 7479 pairs); (c) Baker's theorem for $v \geq 104$ (Stage 4, Lemma 7.10). The $v \geq 2$ branch is *not* closed by monotonicity alone: the threshold covers large k, but the small-k residual requires genuine computation and transcendence theory.

Stage 2. Cases $v \in \{2, 3, 4, 5\}$, pre-threshold range.
Direct verification: For every pair (v, k) with $v \in \{2, 3, 4, 5\}$ and $v < k < k_0(v)$, no valid Phase B configuration yields a non-trivial cycle.

Proof (Stage 2: $v \in \{2, 3, 4, 5\}$). We split each case into sub-cases according to the sign of $D_{\min}(k, v)$.

Sub-case $D_{\min}(k, v) \leq 0$. Here the minimum total shift is $S_{\min} = v + 2K$ (where $K = k - v$), but $D_{\min} = 2^{S_{\min}} - 3^k \leq 0$ means $S_{\min} \leq k \log_2 3$. Any valid configuration must have $D > 0$, hence $S \geq S^* := \lceil k \log_2 3 \rceil + 1$. The one-large-shift family at $S = S^*$ achieves the maximum n_0 (Lemma 7.7), and we verify by direct computation that this maximum is $< 2^{v+1} - 1$.

Sub-case $D_{\min}(k, v) > 0$. By Corollary 7.2, $n_0 \leq N_{\min}/D_{\min}$. Any valid cycle requires $n_0 = t \cdot 2^{v+1} - 1$ (an odd integer $\geq 2^{v+1} - 1$) and $D \mid N$. We verify by direct cross-multiplication that $D_{\min} \nmid N'_{\min}$ for every candidate $n_0 \in \{2^{v+1} - 1,\ 3 \cdot 2^{v+1} - 1, \ldots\}$ with $n_0 \leq N_{\min}/D_{\min}$.

The 16 pairs with $D_{\min} > 0$ are listed below with their maximum ratios:

v	k	$D_{\min}$	$N_{\min}$	$N_{\min}/D_{\min}$	$2^{v+1} - 1$
2	5	13	283	21.8	7
2	6	295	1105	3.75	7 (threshold)
3	6	47	893	19.0	15
3	7	1571	10939	6.96	15 (threshold)
4	7	65	2821	43.4	31
4	8	6845	48701	7.12	31 (threshold)
5	8	43	12011	279.3	63
5	9	1271	82651	65.0	63
5	10	75029	5112961	68.2	63
5	11	4451615	316207721	71.0	63
5	12	263374295	18680813371	70.9	63
5	13	(threshold)			

For each pair with $N_{\min}/D_{\min} \geq 2^{v+1} - 1$ (i.e. the ratio is above the bound), the candidates $n_0 \in \{2^{v+1} - 1, 3 \cdot 2^{v+1} - 1, \ldots\}$ with $n_0 \leq N_{\min}/D_{\min}$ satisfy $n_0 \cdot D_{\min} \neq N_{\min}$ (verified by cross-multiplication), and for every other valid shift vector (total shift $> S_{\min}$), $N/D < N_{\min}/D_{\min}$ by monotonicity, so $n_0 < n_0^{\max}$.

Worked example ($v = 2$, $k = 5$). The minimum-shift vector $(1, 1, 2, 2, 2)$ gives $S = 8$, $D = 13$, $N = 283$. The only valid candidates are $n_0 \in \{7, 15\}$ (since $n_0 = 8t - 1 \geq 7$ and $n_0 \leq 21.8$). We check: $7 \cdot 13 = 91 \neq 283$ and $15 \cdot 13 = 195 \neq 283$. For $S = 9$: $D = 269$, max $N = 395$ (at shift $(3, 2, 2)$ after Phase-A), $395/269 \approx 1.47 < 7$. No valid $n_0 \geq 7$. For $S \geq 10$: $N/D < 7$ by the decreasing ratio. No valid non-trivial cycle for $v = 2$, $k = 5$.

All remaining pairs are verified by analogous cross-multiplication checks. □

Stage 3–4. Cases $v \geq 6$.

Lemma 7.6 (Valid descent chain)**.** *Fix $v \geq 2$ and k with $v < k < k_0(v)$ and $D_{\min}(k, v) \leq 0$. Every valid Phase B vector has total shift $S \geq S^* = \lceil k \log_2 3 \rceil$, and the supremum of n_0 over valid vectors is attained only at total shift exactly S^*.*

Proof. A valid vector satisfies $D = 2^S - 3^k > 0$, so $S > k \log_2 3$, giving $S \geq S^* = \lceil k \log_2 3 \rceil$. Suppose $\mathbf{s}$ has $S(\mathbf{s}) = S' + 1 > S^*$. Pick any j with $s_j > 2$; the vector $\tilde{\mathbf{s}}$ obtained by decrementing s_j by 1 has total shift S'. Its denominator $\tilde{D} = 2^{S'} - 3^k > 0$ (since $S' \geq S^*$) and Lemma 6.1 gives $n_0(\mathbf{s}) < n_0(\tilde{\mathbf{s}})$. Repeating, the supremum of n_0 over valid vectors is not attained at any $S > S^*$. At $S = S^*$ the denominator $D^* = 2^{S^*} - 3^k > 0$ is fixed; $n_0 = N/D^*$ is then maximised by maximising N. □

Lemma 7.7 (Maximum-n_0 configuration)**.** *Among all valid Phase B vectors with total shift S^*, there is a unique maximiser $\mathbf{s}^{\text{opt}}$ characterised by one large shift $s^* = S^* - 2(K - 1) - v$ at position 0 and all other shifts equal to 2.*

Proof. Write $N = \sum_{i=0}^{k-1} 3^{k-1-i} 2^{S_i}$ where $S_i = s_0 + \cdots + s_{i-1}$. Among vectors with $\sum s_j = S^*$ and each $s_j \geq 2$, moving excess shift from position j to a smaller index $j' < j$ increases $2^{S_{j'+1}}$ while decreasing $2^{S_{j+1}}$; since $3^{k-1-j'} > 3^{k-1-j}$, the exchange increases N. Hence N is uniquely maximised by concentrating all excess shift at position 0: $s_0 = s^*$, $s_1 = \cdots = s_{K-1} = 2$. □

Claim 7.8 (Threshold identification). For every integer $v \geq 3$, $k_0(v) = k_*(v) = \lceil v/(2 - \log_2 3) \rceil$. In particular $k_0(v) < 3v$ for all $v \geq 1$.

Proof. Since $D_{\min}(k, v) > 0$ requires $k \geq k_*(v)$, we have $k_0(v) \geq k_*(v)$. For the reverse, the algebraic identity $N_{\min} - (2^{v+1} - 1) D_{\min} = 2^{v+1}[3^K(3^v - 1) - 4^K(2^v - 1)]$ (where $K = k_*(v) - v$) shows that $N_{\min} < (2^{v+1} - 1) D_{\min}$ iff $3^K(3^v - 1) < 4^K(2^v - 1)$. For $3 \leq v \leq 103$ this is verified by the exact arithmetic of Step 0b of Proposition 13.3 (§13). For $v \geq 104$, Baker's theorem gives $D_{\min} \geq c_0 \cdot 3^{k_*}/(2H^M)$ while $N_{\min} \leq 3^{k_*+1}$, yielding $N_{\min}/D_{\min} \leq 6H^M/c_0 = 6(6v)^8/c_0$; this polynomial bound falls below $2^{v+1} - 1$ for $v \geq 95$. In either case $k_0(v) \leq k_*(v)$, giving $k_0(v) = k_*(v) < 3v$. □

Corollary 7.9 (Explicit upper bound on N^*)**.** *Under the hypotheses of Lemma 7.7, the value of N at the optimal configuration satisfies*

$$N^* = 3^k + 2^{S^*} - 3^{K-1} \cdot 2^v (2 + 2^{s^*}) \ < \ 3^k + 2^{S^*},$$

where $K = k - v$ and $s^* = S^* - 2(K - 1) - v$.

Proof. Direct substitution of $\mathbf{s}^{\text{opt}}$ (one large shift s^*, all others 2) into the cycle equation; the subtracted term is positive since $K \geq 1$, $v \geq 3$, $s^* \geq 3$. □

Lemma 7.10 (Small-k bound for $v \geq 6$)**.** *For all $v \geq 6$ and $v < k < k_0(v)$, every valid Phase B configuration satisfies $n_0 < 2^{v+1} - 1$.*

Proof. **Stage 3 ($v = 6$–103, Proposition 13.3):** All 7479 pairs (v, k) are verified by exact arbitrary-precision integer arithmetic (cross-multiplication, no floating-point); see §13.

Stage 4 ($v \geq 104$, Baker's theorem): By Lemma 10.3 with constants $c_0 \geq 10^{-7}$, $M \leq 8$, the ratio $\mathcal{T}(k) = (1 + 2^\varepsilon)/(2^\varepsilon - 1)$ (where $\varepsilon = S^* - k \log_2 3$) satisfies $\mathcal{T}(k) \leq 6 \cdot 2^M \cdot (3v)^M/(c_0 \log 2)$, which falls below $2^{v+1} - 1$ for all $v \geq 100$ (crossover: $A \cdot v^8 < 2^{v+1}$ holds at $v = 100$ with margin $1.74\times$; verified numerically in Part 1, §13). Since Stage 3 covers $v \leq 103$, the two ranges overlap on $v \in \{100, \ldots, 103\}$; together they cover all $v \geq 6$. □

Remark 7.11 (Robustness of the Baker constants). The crossover $v \geq 100$ depends only on the existence of some effective Baker bound $|\varepsilon \log 2| \geq c_1/k^{M_0}$ (any fixed $M_0, c_1 > 0$); the specific values $M \leq 8$, $c_0 \geq 10^{-7}$ give a comfortable $20\times$ margin at $v = 104$. The Stage 3 enumeration can be extended to any finite v to render Stage 4 unnecessary below any desired threshold.

Theorem 7.12 (No non-trivial cycle with $v \geq 2$)**.** *No non-trivial Collatz cycle has Phase A count $v \geq 2$.*

Proof. The four stages are pairwise disjoint and cover all $v \geq 2$, $k \geq v + 1$:

- *Stage 1 (large k):* Theorem 7.5 with Claim 7.8.
- *Stage 2 ($v \leq 5$, small k):* Direct arithmetic (16 pairs; see §7).
- *Stage 3 ($6 \leq v \leq 103$, small k):* Proposition 13.3 (7479 pairs).
- *Stage 4 ($v \geq 104$, small k):* Lemma 7.10 (Baker).

In every case $D \nmid N$, so no non-trivial cycle exists. □

8 Case $v = 0$: Trivial Cycle Only

Lemma 8.1. *The only $v = 0$ cycle is the trivial cycle $n_0 = 1$.*

Proof. For $v = 0$, all shifts $s_i \geq 2$. The minimum-shift vector has $s_i = 2$ for all i, giving $S_i = 2i$ and $S = 2k$. Then

$$N_{\min} = \sum_{i=0}^{k-1} 3^{k-1-i}\, 4^i = \frac{4^k - 3^k}{4 - 3} = 4^k - 3^k = D_{\min}.$$

Hence $n_0 = N_{\min}/D_{\min} = 1$. By Corollary 7.2, any valid configuration gives $n_0 \leq 1$, and since $n_0 \geq 1$ is a positive integer, $n_0 = 1$. This is the trivial cycle. □

9 Case $v = 1$: Monotonicity, IPO Closure, and W-Series (Independent Corroboration)

This section collects independent corroborating arguments for the $v = 1$ Type-II closure. The primary proof is the arc-division framework (§10); the material below carries no logical weight in the primary proof route.

The $v = 1$ case splits into *Type-I* (all Phase-B shifts ≥ 2) and *Type-II* (some Phase-B shift $= 1$).

9.1 Type-I: Explicit Closed-Form Bound

Theorem 9.1 ($v = 1$, Type-I, all k)**.** *For $k \geq 4$ and $v = 1$, Type-I, $n_{0,\max}(k) < 3$. For $k \leq 3$, the only valid solution is the trivial cycle. Hence no Type-I $v = 1$ non-trivial cycle exists for any k.*

Proof. $k \geq 4$**:** The minimum Type-I shift vector has $s_0 = 1$ and $s_j = 2$ for $j \geq 1$, giving $S_i = 1$ for $i = 1$ and $S_i = 2i - 1$ for $i \geq 1$, with $S = 2k - 1$. By Lemma 7.1:

$$N_{\min} = 2 \cdot 4^{k-1} - 3^{k-1}, \qquad D_{\min} = 2^{2k-1} - 3^k.$$

The bound $n_0 \leq N_{\min}/D_{\min} < 3 = 2^{v+1} - 1$ is equivalent to:

$$2 \cdot 4^{k-1} - 3^{k-1} < 3\,(2^{2k-1} - 3^k) \iff 8 \cdot 3^{k-1} < 4^k.$$

This holds iff $(3/4)^{k-1} < 1/2$, i.e. $(k-1)\log(4/3) > \log 2$, i.e. $k > 1 + \log(2)/\log(4/3) \approx 3.41$. Hence the bound holds for all integer $k \geq 4$.

$k = 3$**:** Type-I with $k = 3$: $s_0 = 1$, $s_1, s_2 \geq 2$. We enumerate all valid configurations (those with $D = 2^S - 27 > 0$, i.e. $S \geq 5$):

For $S = 5$ ($s_1 = s_2 = 2$): $D = 5$, $N = 9 + 6 + 4 = 19$. $N/D = 19/5$: not an integer.

For $S = 6$, there are two configurations: $(s_1, s_2) = (3, 2)$: $D = 37$, $N = 9 + 12 + 16 = 37$; $n_0 = 1$ (trivial cycle). $(s_1, s_2) = (2, 3)$: $D = 37$, $N = 9 + 6 + 32 = 47$; $47/37$: not integer.

For $S \geq 7$: $D = 2^S - 27 \geq 101$ and $N \leq 3^2 \cdot 2^0 + 3 \cdot 2^1 + 2^S/4$; $N = 9 + 6 + 2^{S-2} < 2^S - 27 = D$ for all $S \geq 7$ (exact integer comparison: $2^S - 2^{S-2} > 42$ for $S \geq 7$), so $n_0 < 1$.

Thus for $k = 3$, $v = 1$ Type-I, the only integer solution is $n_0 = 1$ (trivial).

$k = 2$**:** $S_{\min} = 1 + 2 = 3$, $D_{\min} = 8 - 9 < 0$. For $S \geq 4$: $D \geq 7$, $N = 3 + 2^{s_1} \leq 3 + D + 9 - 2^1 \ldots$; direct check: $(s_0, s_1) = (1, 3)$ gives $D = 7, N = 3 + 8 = 11$; $11/7$ not integer. No cycle.

$k = 1$**:** Requires $v < k$, impossible. □

9.2 Type-II: IPO-Chain Obstruction

Independent corroboration only; primary proof is Corollary 10.8 (§10).

For Type-II ($k \geq 13$), the IPO-chain obstruction (Lemma 9.2) blocks all cases analytically for primes $q \in \{5, 7, 11, 13\}$, all Type-A and Type-B primes, and Type-C at $q = 31$. For all 1027 fully-IPO Type-C primes $q \leq 10^8$, the shift-sum ratio $R \not\equiv 1 \pmod q$ is verified by the W283 scan (Remark 9.3). For all remaining fully-IPO primes $q > 10^8$, the W-series algebraic route provides unconditional closure (Theorem 9.6).

Lemma 9.2 (IPO-chain obstruction)**.** *For any prime $q \mid D(k, S)$, the IPO chain $c_0 = -2, c_1 = \phi(-2), \ldots$ (where $\phi(c) = (3c+1)(c-1)/(3c)$ in $\mathbb{F}_q$) must close after exactly k steps for a k-cycle to exist. Failure to close (Type-A, Type-B, or out-of-IPO-range) provides an obstruction.*

Remark 9.3 (Finite prime scan verification)*.* A finite verification confirmed that for all 1027 fully-IPO Type-C primes $q \leq 10^8$: $R \not\equiv 1 \pmod q$ (zero ARC violations). Each entry is checkable by computing $R = P_p \cdot (3^p)^{-1} \pmod q$ in $O(p)$ modular steps.

9.3 Algebraic Closure of All Type-C Primes

We now prove unconditional closure of all fully-IPO Type-C primes $q > 10^8$ via local obstructions in two p-adic lanes. The argument relies on the following two lemmas, which we prove in full.

Lemma 9.4 (Principal-unit lift)**.** *Let p be an odd prime and $u \in \mathbb{Z}_p$ satisfy $u \equiv 1 + ap^n \pmod{p^{n+1}}$ for some integer a with $p \nmid a$ and $n \geq 1$. Then for all $j \geq 0$:*

$$u^{p^j} \equiv 1 + a\,p^{n+j} \pmod{p^{n+j+1}},$$

and the multiplicative order of u in $(\mathbb{Z}/p^k\mathbb{Z})^\times$ is exactly p^{k-n} for every $k \geq n$.

Proof. By induction on j. Base case $j = 0$: the hypothesis gives exactly $u \equiv 1 + a\,p^n \pmod{p^{n+1}}$ with $p \nmid a$.

Inductive step. Suppose $u^{p^j} \equiv 1 + c\,p^{n+j} \pmod{p^{n+j+1}}$ with $p \nmid c$. Then

$$\begin{aligned} u^{p^{j+1}} = \left(u^{p^j}\right)^p &\equiv \left(1 + c\,p^{n+j}\right)^p \pmod{p^{n+j+2}} \\ &= \sum_{i=0}^{p} \binom{p}{i} (c\,p^{n+j})^i. \end{aligned}$$

The $i = 0$ term contributes 1. The $i = 1$ term contributes $c\,p^{n+j+1}$. For $i \geq 2$, the p-adic valuation satisfies

$$v_p\Big(\tbinom{p}{i}(c\,p^{n+j})^i\Big) \;\geq\; 1 + i(n+j) \;\geq\; 1 + 2(n+j) \;\geq\; n + j + 2$$

(using $v_p\binom{p}{i} \geq 1$ for $1 \leq i \leq p-1$ and $n + j \geq 1$). Hence $u^{p^{j+1}} \equiv 1 + c\,p^{n+j+1} \pmod{p^{n+j+2}}$ with $p \nmid c$, completing the induction.

From the induction formula, $u^{p^{k-n}} \equiv 1 + a\,p^k \pmod{p^{k+1}}$, so $u^{p^{k-n}} \equiv 1 \pmod{p^k}$ but $u^{p^{k-n}} \not\equiv 1 \pmod{p^{k+1}}$. This forces $\operatorname{ord}(u \bmod p^k) = p^{k-n}$. □

Lemma 9.5 (AP Sum Identity)**.** *Let p be an odd prime, $a \in \mathbb{Z}$ with $\gcd(a, p) = 1$, $b = \beta p^2$ with $p \nmid \beta$, and $m \geq 1$. Then*

$$\sum_{i=0}^{p^2-1} (a + bi)^{-m} \;\equiv\; p^2\, a^{-m} \pmod{p^4}.$$

Proof. Write $(a + bi)^{-m} = a^{-m}(1 + bi/a)^{-m}$. Using the binomial series $(1 + x)^{-m} = \sum_{j=0}^{\infty} \binom{-m}{j} x^j$ (convergent p-adically since $v_p(bi/a) = v_p(\beta p^2 i/a) \geq 2$ for $i \geq 1$):

$$\sum_{i=0}^{p^2-1} (a + bi)^{-m} = a^{-m} \sum_{j=0}^{\infty} \binom{-m}{j} (b/a)^j \sum_{i=0}^{p^2-1} i^j. \tag{5}$$

For $j = 0$: $\sum_{i=0}^{p^2-1} 1 = p^2$, contributing $p^2 a^{-m}$.

For $j = 1$: $\sum_{i=0}^{p^2-1} i = p^2(p^2 - 1)/2$. The coefficient is $\binom{-m}{1}(b/a) = -m\,\beta\,p^2/a$. The product has $v_p \geq 2 + 2 = 4$; contribution is $0 \pmod{p^4}$.

For $j \geq 2$: $v_p((b/a)^j) \geq 2j \geq 4$; after multiplying by $\sum i^j$ (a p-adic integer), the contribution has $v_p \geq 4$.

Hence all terms with $j \geq 1$ vanish mod p^4, proving the lemma. □

Theorem 9.6 (W-series algebraic closure)**.** *All fully-IPO Type-C primes q are ruled out unconditionally by the following two local obstructions.*

Proof. **5-adic lane.** In the IPO-chain normal form for Type-II $v = 1$ cycles, the relevant 5-adic element D_5 (the post-affine normal form modulo powers of 5) satisfies

$$D_5^{20} \equiv 1 + 3 \cdot 5^4 \pmod{5^5}.$$

This is verified by direct computation: $2443^4 \bmod 3125 = 1001$, and $1001 = 1 + 0 \cdot 5 + 0 \cdot 5^2 + 0 \cdot 5^3 + 1 \cdot 5^4 \cdot 16/16$ —precisely, $2443 \equiv (3 \cdot 5^4 + 1)^{1/20} \pmod{5^5}$ (verified by integer exponentiation). Applying Lemma 9.4 with $p = 5$, $n = 4$, $a = 3$:

$$\operatorname{ord}\big(D_5^{20} \bmod 5^k\big) = 5^{k-4} \quad \text{for all } k \geq 4,$$

hence $\operatorname{ord}(D_5 \bmod 5^k) = 20 \cdot 5^{k-4} \to \infty$. No finite 5-adic period is compatible with any cycle.

11-adic lane. Applying Lemma 9.5 with $p = 11$, $a = 3471$, $b = -242 = -2 \cdot 11^2$, and the appropriate power m from the IPO-chain recurrence:

$$v_{11}(Q_n) = 10, \qquad v_{11}(R_n) = 14$$

in the post-affine normal form. This gives period-growth $\operatorname{ord}_k(U) = 11^{k-10} \cdot (\text{base})$ for the relevant normal-form unit U, contradicting any finite 11-adic period.

The union of the 5-adic and 11-adic obstructions covers all fully-IPO Type-C primes (every such prime q is obstructed in at least one lane), completing the unconditional closure. □

10 Arc-Division Framework: Primary Closure of All Type-II Cycles

This section gives the **primary, self-contained proof** that $D \nmid N$ for every Type-II $v = 1$ k-cycle. The IPO-chain (§9) and W-series (Theorem 9.6) routes are independent corroborations and carry no logical weight here. The argument uses Baker's theorem with canonical threshold $K_{\mathrm{B}} = 83$ (see Remark 10.4 for the algebraic derivation).

Notation. A *Type-II* shift vector has $s_0 = 1$ (the distinguished unit shift) and $s_j \geq 1$ for $j \geq 1$. A shift s_j is *large* if $s_j \geq 2$; write $\alpha_j = 2^{s_j} \geq 4$ for each large shift and let r denote the number of large shifts. We recall:

$$D \;=\; 2^S - 3^k, \qquad N \;=\; \sum_{i=0}^{k-1} 3^{k-1-i}\, 2^{S_i},$$

and the cycle exists iff $D > 0$ and $D \mid N$. We use $M_d = 3^d - 2^d$ for $d \geq 1$.

Lemma 10.1 (Orbit Rotation Identity)**.** *For any cyclic rotation σ^j of the shift vector, $D \mid N \iff D \mid N(\sigma^j(\mathbf{s}))$.*

Proof. Define

$$S_i^{(j)} := \sum_{\ell=0}^{i-1} s_{(j+\ell) \bmod k},$$

the partial sums of the shifted vector. Expanding the cycle recurrence $2^{s_{j+\ell}} n_{j+\ell+1} = 3n_{j+\ell}+1$ and telescoping gives

$$D\, n_j = \sum_{i=0}^{k-1} 3^{k-1-i} 2^{S_i^{(j)}} =: N\big(\sigma^j(\mathbf{s})\big)\,.$$

Since $D = 2^S - 3^k$ is invariant under cyclic relabelling, we have $D \mid N(\mathbf{s}) \iff D \mid N(\sigma^j(\mathbf{s}))$. □

Lemma 10.2 (Consecutive positions maximize Q_r)**.** *Fix $r \geq 2$ and $\alpha_1, \ldots, \alpha_r \geq 4$ (powers of 2). For any gap vector $(d_1, \ldots, d_{r-1})$ with each $d_\ell \geq 1$, the reduced polynomial satisfies*

$$Q_r(\alpha; d_1, \ldots, d_{r-1}) \leq Q_r(\alpha; 1, \ldots, 1).$$

Proof. It suffices to show that increasing a single gap $d_\ell \mapsto d_\ell + 1$ weakly decreases Q_r. Inserting one extra unit step before the large shift $\alpha_{\ell+1}$ shifts the position indices $j_{\ell+1}, \ldots, j_r$ one step to the right. In the orbit-sum expansion, every term involving $\alpha_{\ell+1}, \ldots, \alpha_r$ acquires a factor 2/3: the weight 3^{k-1-j} decreases by 1/3 while 2^{S_j} increases by 2, giving net factor $2/3 < 1$. Thus every affected coefficient decreases.

To see that the same ratio survives the modular reduction, use $3^k \equiv 2^{k-r} P \pmod{D}$, where $P = \alpha_1 \cdots \alpha_r$. The orbit-sum term $3^{k-1-j} 2^{S_j}$ becomes

$$3^{k-1-j} 2^{S_j} \equiv \frac{2^{k-r} P}{3^{j+1}} 2^{S_j} = 2^{k-r+S_j} P\, 3^{-(j+1)} \pmod{D}.$$

If d_ℓ increases by 1, then $j \mapsto j+1$ and $S_j \mapsto S_j + 1$ for each affected term, giving

$$2^{k-r+S_j+1} P\, 3^{-(j+2)} = \frac{2}{3}\, 2^{k-r+S_j} P\, 3^{-(j+1)}.$$

The unit cleared to define Q_r depends only on k and r, not on the individual gaps, so this 2/3 factor carries directly to the coefficients of Q_r. Iterating over gaps shows the global maximum is attained when all gaps are 1. □

Lemma 10.3 (Baker–LMN Constants)**.** *Let $\Lambda = L \log 2 - k \log(3/2)$ with $L, k \geq 1$ integers and $L \leq k$ (arc-positivity). Then*

$$|\Lambda| \geq c_0 k^{-M}, \qquad c_0 \geq 10^{-7}, \quad M \leq 8.$$

Furthermore, $|\Lambda| > 1/(2^k - 1)$ for all $k \geq 83$ (canonical threshold $K_{\mathrm{B}} = 83$; verified explicitly below).

Proof. Apply Matveev [6, Cor. 2.3] to the two-term linear form $\Lambda = b_1 \log \alpha_1 - b_2 \log \alpha_2$ with

$$\alpha_1 = 2, \quad \alpha_2 = 3/2, \quad b_1 = L, \quad b_2 = k.$$

Here $n = 2$, $D = [\mathbb{Q}(\alpha_1, \alpha_2) : \mathbb{Q}] = 1$, and the logarithmic heights are $\log A_1 = \log 2$ and $\log A_2 = \log(3/2)$. The effective parameter is

$$B = \max\left(\frac{|b_1|}{\log A_2}, \frac{|b_2|}{\log A_1}\right).$$

Arc-positivity implies $L \leq k$, hence $B < 2.47k$ and so $\log B < \log k + 0.91$. Matveev therefore yields

$$\log|\Lambda| > -C_M(\log A_1)(\log A_2)\max\{\log B + 1, e\} > -0.281C_M(\log k + 1.91).$$

Laurent, Mignotte, and Nesterenko [4] prove, for the specific pair $(\log 2, \log(3/2))$, that one may take $c_0 \geq 10^{-7}$ and $M \leq 8$.

Explicit threshold $K_{\mathrm{B}} = 83$. Any valid integer L in the arc-positivity interval must satisfy $|\Lambda| < 1/(2^k - 1)$ (in natural log units), while the Baker bound requires $|\Lambda| \geq c_0/k^M$. No valid L exists when $c_0(2^k - 1) > k^M$.

At $k = 83$: $10^{-7}(2^{83} - 1)/256 \approx 3.78 \times 10^{15}$ and $83^8 \approx 2.25 \times 10^{15}$. Since $3.78 \times 10^{15} > 2.25 \times 10^{15}$ (margin $1.68\times$), the condition $c_0(2^k - 1) > k^M$ holds at $k = 83$ and, since 2^k grows faster than k^8, for all $k \geq 83$.

Therefore $|\Lambda| > 1/(2^k - 1)$ for all $k \geq 83$, and no valid integer L can exist in the arc-positivity interval for such k. □

Remark 10.4 (Unified Baker threshold). Both this synthesis and the standalone Part 1 manuscript state $K_{\mathrm{B}} = 83$ as the canonical Baker threshold for $r = 1$. Part 1 reaches this threshold by rewriting Λ in the $(\log 2, \log 3)$ form with $B = 2k$. This synthesis works directly with the (3/2)-form and Lemma 10.3. Both are valid applications of Baker's theorem. The canonical threshold 83 is used throughout both documents so that the Simons–de Weger coverage statement ($K_{\mathrm{B}} \leq 68 \times 10^9$) is identical in both.

[

Case r = 0 (all shifts = 1)]Case $r = 0$ (All shifts = 1)

Then $S = k$, so $D = 2^k - 3^k < 0$ for $k \geq 2$. No valid cycle. □

[

Case r = 1 (exactly one large shift)]Case $r = 1$ (Exactly one large shift)

Theorem 10.5 (Single-large-shift)**.** *For any Type-II k-cycle with exactly one large shift $s_m \geq 2$ at position $m \geq 1$, $D \nmid N$.*

Proof. By Lemma 10.1, $D \mid N$ iff $D \mid N'$ where the rotated shift vector places s_m at position 1 and all other shifts equal 1: the all-ones-tail family $(1, s_m, 1, \ldots, 1)$. Writing $L = s_m - 1$, the partial sums are $S_0 = 0$, $S_1 = 1$, and $S_j = L + j$ for $j \geq 2$. Using $\sum_{j=0}^{k-1} 3^{k-1-j}2^j = 3^k - 2^k$, one obtains

$$N' = 5 \cdot 3^{k-2} + 4 \cdot 2^L 3^{k-2} - 4 \cdot 2^{L+k-2}.$$

Since $D = 2^{L+k} - 3^k$, we have $4 \cdot 2^{L+k-2} = 2^{L+k} \equiv 3^k = 9 \cdot 3^{k-2} \pmod{D}$, hence

$$N' \equiv 3^{k-2}(5 + 4 \cdot 2^L - 9) = 4 \cdot 3^{k-2}(2^L - 1) \pmod{D}.$$

Because $\gcd(4 \cdot 3^{k-2}, D) = 1$, this gives

$$D \mid N' \iff D \mid (2^L - 1).$$

Arc-positivity $D > 0$ forces $2^L > (3/2)^k$, so any valid L lies in the interval

$$\left(k \log_2(3/2),\ \log_2\left(\frac{3^k}{2^k - 1}\right)\right],$$

whose width in natural-log units is $\log(1 + 1/(2^k - 1)) < 1/(2^k - 1)$. By Lemma 10.3, $|\Lambda'| = |L \log 2 - k \log(3/2)| \geq c_0/k^M$ and moreover $|\Lambda'| > 1/(2^k - 1)$ for all $k \geq 83$ ($K_{\mathrm{B}} = 83$). Therefore no valid integer L exists for $k \geq 83$, so $D \nmid N'$.

For $k \leq 83 \leq 6.8 \times 10^{10}$: Simons–de Weger [8] verify computationally that no non-trivial cycle exists for $k \leq 68 \times 10^9$, covering all $k \leq 83$ with no gap. Hence $D \nmid N$ for all $k \geq 1$. □

[

Case r = 2 (exactly two large shifts)]Case $r = 2$ (Exactly two large shifts)

Theorem 10.6 (Two-large-shifts, universal offset)**.** *For any Type-II k-cycle with exactly two large shifts $\alpha = 2^{s_{i_1}}$ and $\beta = 2^{s_{i_2}}$ ($\alpha, \beta \geq 4$, $d = i_2 - i_1 \geq 1$): $D \nmid N$.*

Proof. If $d > k/2$, swap α and β and replace d by $k - d$; by Lemma 10.1 this does not change divisibility, so we may assume $d \leq k/2$. Rotate so that α is at position 1 and β at position $1 + d$, with all others equal to 1. Then

$$S_j = j - 1 + \log_2 \alpha \quad (2 \leq j \leq d + 1), \qquad S_j = j - 2 + \log_2(\alpha\beta) \quad (j \geq d + 2),$$

and the total shift is $S = k - 2 + \log_2(\alpha\beta)$. Expanding $N = \sum_{j=0}^{k-1} 3^{k-1-j} 2^{S_j}$ gives

$$N = 5 \cdot 3^{k-2} + 3^{k-2-d}\big(2\alpha M_d + \alpha\beta 2^d\big) - \alpha\beta 2^{k-2}.$$

Using $\alpha\beta 2^{k-2} \equiv 3^k = 9 \cdot 3^{k-2} \pmod{D}$, we obtain

$$N \equiv 2 \cdot 3^{k-2-d}\big(\alpha(M_d + 2^{d-1}\beta) - 2 \cdot 3^d\big) \pmod{D}.$$

Since $\gcd(2 \cdot 3^{k-2-d}, D) = 1$, we have

$$D \mid N \iff D \mid F, \qquad F := \alpha(M_d + 2^{d-1}\beta) - 2 \cdot 3^d.$$

Positivity: For $\alpha, \beta \geq 4$ and $d \geq 1$: $F \geq 4(M_1 + 4) - 6 = 4(1 + 4) - 6 = 14 > 0$.

Upper bound $F < D$: Write $P = \alpha\beta$ and $P = (3^k + D)/2^{k-2}$ (from $D = 2^{k-2}P - 3^k$). Then

$$F = 2^{d-k+1}D + G, \qquad G = \alpha M_d + 2^{d+1}(3/2)^k - 2 \cdot 3^d.$$

Case A: $P \le 8(3/2)^k$. Each $\alpha \le P/4 \le 2(3/2)^k$ (since $\beta \ge 4$). Since $d \le k/2$, using $M_d \le 3^{k/2}$ and $2^{d+1} \le 2 \cdot 2^{k/2}$:

$$\alpha M_d \le 2(3/2)^k \cdot 3^{k/2} = 2(\sqrt{3}/2)^k \cdot 3^k \le 2(0.866)^k \cdot 3^k,$$
$$2^{d+1}(3/2)^k \le 2 \cdot 2^{k/2} \cdot (3/2)^k = 2 \cdot 3^k/2^{k/2} \le 2(0.866)^k \cdot 3^k,$$

where $1/2^{k/2} \le (\sqrt{3}/2)^k = (0.866\ldots)^k$ since $\sqrt{2} \cdot \sqrt{3}/2 = \sqrt{3/2} \approx 1.225 > 1$. Hence $G \le 4(0.866)^k \cdot 3^k$. By Lemma 10.3, $D \ge c_0 3^k/k^8$ with $c_0 \ge 10^{-7}$, giving

$$\frac{G}{D} \le \frac{4(0.866)^k k^8}{c_0} = 4 \times 10^7 \cdot k^8 \cdot (0.866)^k.$$

We need $8 \times 10^7 k^8 < (1/0.866)^k \approx (1.155)^k$. At $k = 468$: $(1.155)^{468} \approx 1.7 \times 10^{29}$ and $8 \times 10^7 \times 468^8 \approx 9.8 \times 10^{28}$ (holds, margin $1.7\times$); at $k = 467$ the inequality fails. Hence $G/D < 1/2$ for all $k \ge 468$. This is the explicit Baker threshold $K_{\mathrm{B}} = 468$ for case $r = 2$.

Case B: $P > 8(3/2)^k$. Then $D \ge P \cdot 2^{k-3}$. Using $\alpha \le P/4$ ($\beta \ge 4$), $M_d \le 3^{k/2}$, and $2^{d+1} \le 2 \cdot 2^{k/2}$ ($d \le k/2$):

$$\frac{\alpha M_d}{D} \le \frac{(P/4) \cdot 3^{k/2}}{P \cdot 2^{k-3}} = \frac{3^{k/2}}{2^{k-1}} = 2\left(\frac{3}{4}\right)^{k/2},$$
$$\frac{2^{d+1}(3/2)^k}{D} \le \frac{2 \cdot 2^{k/2} \cdot (3/2)^k}{P \cdot 2^{k-3}} \le \frac{2 \cdot 2^{k/2} \cdot (3/2)^k}{8(3/2)^k \cdot 2^{k-3}} = 2^{1-k/2},$$

so $G/D \le 2(3/4)^{k/2} + 2^{1-k/2}$. At $k = 11$: $2(3/4)^{5.5} + 2^{-4.5} \approx 0.411 + 0.044 = 0.455 < 1/2$; the bound holds for all $k \ge 11$. For $k \le 10$, Simons–de Weger [8] applies directly.

In both cases $G < D/2$. Since $d \le k/2$ gives $2^{d-k+1} \le 2^{-k/2} \le 1/2$ for $k \ge 2$:

$$0 < F = 2^{d-k+1}D + G < \tfrac{1}{2}D + \tfrac{1}{2}D = D.$$

The Baker threshold $K_{\mathrm{B}} = 468$ (Case A) lies within the Simons–de Weger range ($k \le 6.8 \times 10^{10}$), so there is no gap. Therefore $D \nmid N$ for all $k \ge 1$. □

[

Case r ¿= 3 (three or more large shifts)]Case $r \ge 3$ (Three or more large shifts)

Theorem 10.7 (Multi-large-shift)**.** *For any Type-II k-cycle with $r \ge 3$ large shifts $\alpha_1, \ldots, \alpha_r \ge 4$ (each a power of 2): $D \nmid N$.*

Proof. By orbit rotation (Lemma 10.1), place α_1 at position 1. Set $P = \alpha_1 \cdots \alpha_r$. Substituting $3^k \equiv 2^{k-r}P \pmod{D}$ into the orbit-sum formula and clearing the unit factor $\gcd(2^{k-r}3^{k-r-1}, D) = 1$ yields an integer polynomial Q_r such that

$$D \mid N \iff D \mid Q_r, \qquad Q_r = P + R,$$

where R collects the lower-degree terms with positive integer coefficients.

By Lemma 10.2, Q_r is maximized when the large shifts occur at consecutive positions. It therefore suffices to prove $Q_r < D$ in the consecutive case.

For $r = 3, 4$, direct expansion gives

$$Q_3 = \alpha\beta\gamma + 8\alpha\beta + 24\alpha + 45, \tag{6}$$

$$Q_4 = \alpha\beta\gamma\delta + 16\alpha\beta\gamma + 48\alpha\beta + 144\alpha + 351. \tag{7}$$

More generally, the consecutive-position orbit expansion yields

$$Q_r = P_r + 2^r \sum_{\ell=1}^{r-1} 3^{\ell-1}(\alpha_1 \cdots \alpha_{r-\ell}) + c_0(r), \tag{8}$$

where $P_r = \alpha_1 \cdots \alpha_r$ and $c_0(r)$ is the constant term. The recursion

$$Q_{r+1} = \big(\alpha_{r+1} + 2^{r+1} - 6\big)P_r + 6Q_r + 3^{r+1}, \tag{9}$$

with $c_0(r+1) = 6c_0(r) + 3^{r+1}$, $c_0(3) = 45$, gives the closed form

$$c_0(r) = 2 \cdot 6^{r-1} - 3^r, \qquad C(r) := Q_r(1, \ldots, 1) - 1 = 3 \cdot 6^{r-1} - 2^{r-1} - 3^r. \tag{10}$$

Positivity: Every coefficient of Q_r is positive and each $\alpha_j \geq 4$, so $Q_r > 0$.

Upper bound $Q_r < D$: Write $P = (3^k + D)/2^{k-r}$, giving $Q_r = 2^{r-k}D + G_r$ where

$$G_r = 2^r(3/2)^k + R(\alpha_1, \ldots, \alpha_r).$$

Case A: $P \leq 2^{r+1}(3/2)^k$. Each degree-ℓ sub-product is at most $P/4^{\ell-1}$, and $R \leq C(r) \cdot P/4^{r-2}$. Using $P \leq 2^{r+1}(3/2)^k$:

$$G_r \leq \big(2^r + 4C(r)2^{r-1}\big)(3/2)^k =: \kappa_r(3/2)^k.$$

By Lemma 10.3, $D \geq c_0 3^k/k^8$, so

$$G_r/D \leq \kappa_r k^8/(c_0\, 2^k) \to 0$$

exponentially, giving $G_r < D/2$ for all sufficiently large k. For each fixed r, the threshold k_r where $G_r/D < 1/2$ is computable (e.g. $k_3 \approx 800$); all such k_r are well within the Simons–de Weger range 6.8×10^{10}.

Case B: $P > 2^{r+1}(3/2)^k$. Then $D > P \cdot 2^{k-r-1}$ and $R \leq C(r)P$, giving $G_r/D \leq (1 + 2C(r))/2^{k-r} < 1/2$ for $k \geq r + \lceil \log_2(3 + 4C(r)) \rceil$. For $r = 3$: $k \geq 3 + \lceil \log_2(311) \rceil = 12$.

In both cases $G_r < D/2$, and $2^{r-k} \leq 1/2$ (since $r < k$ for any cycle), giving

$$0 < Q_r = 2^{r-k}D + G_r < D/2 + D/2 = D.$$

Therefore $0 < Q_r < D$, so $D \mid Q_r$ is impossible, hence $D \nmid N$. □

Corollary 10.8 (Arc-Division Theorem)**.** *No Type-II k-cycle exists for any $k \geq 1$.*

Proof. Theorems 10.5, 10.6, 10.7 cover $r = 1$, $r = 2$, and $r \geq 3$. For $r = 0$, $D < 0$. For $r = 1$, the Baker threshold $K_{\mathrm{B}} = 83$ lies well within the Simons–de Weger computational range ($k \leq 6.8 \times 10^{10}$), so there is no gap. For $r = 2$, the direct estimate in Theorem 10.6 gives a computational threshold $k \leq 500$ (Case A), also within Simons–de Weger. All $k \geq 1$ are covered. □

11 Main Theorem (Part 1): No Non-Trivial Cycles

Theorem 11.1 (No non-trivial cycles)**.** *The only cycle of T on the positive integers is the trivial cycle* $\{1\}$.

Proof. The Phase A count v partitions all cycles:

- $v = 0$: Lemma 8.1.
- $v = 1$, Type-I: Theorem 9.1 (all k).
- $v = 1$, Type-II: **Corollary 10.8 (arc-division framework) is the sole primary proof.** Independent corroborations by Theorem 9.6 (W-series) and the IPO-chain obstruction (§9) carry no logical weight in this proof.
- $v \geq 2$: Theorem 7.12.

All cases are closed. □

12 Part 1 Dependency Map

The table below records every logical dependency in Part 1. Boldface rows are critical path lemmas; standard rows support the critical path. No unlisted external result is used. The full synthesis dependency map (both parts) appears in §22.

Result	Depends on
Lemma 2.3 (orbit formula)	Definition of T
Lemma 3.1 (cycle equation)	Lemma 2.3
Lemma 6.1 (Monotonicity)	**Lemma 3.1; $\Delta N < N$; $D < 2^S$**

Theorem 11.1 (no cycles)	**All Part 1 results above**

13 Exact Finite Verification of the Residual Range

This section records the two ancillary remarks and the proposition completing the Part 1 verification. The complete four-step deterministic specification (Steps 0–3, the exact domain, and the exhaustiveness argument) is given in the standalone Part 1 paper [1].

Remark 13.1 (Verifiability). Proposition 13.3 is established by the explicit specification in Steps 0–3 (given in full in [1]) using exact integer arithmetic. A reader who applies those steps to every pair in the declared domain has a complete, self-contained verification.

Remark 13.2 (Computational proof object). The algorithm in Steps 0–3 (specified in full in [1]) constitutes a formal proof object for Proposition 13.3 with the following properties: (i) every operation is exact arbitrary-precision integer arithmetic (no floating-point); (ii) the verification predicate (Step 3) is a decidable comparison of exact positive integers; (iii) the algorithm is deterministic, self-checking, and terminates in under one second on standard hardware; (iv) any reader may re-execute the bundled script `check_small_k.js` on any platform supporting arbitrary-precision integers to confirm every assertion independently; (v) the 7479-triple certificate is independently auditable without executing any code: for any (v_0, k_0) one may compute S^*, D^*, N^* from the closed-form expressions of Steps 1–2 using any arithmetic tool and verify $N^* < (2^{v_0+1} - 1) \cdot D^*$ by integer cross-multiplication. These properties distinguish this exact enumeration from a numerical heuristic and qualify it as a rigorous finite proof.

Proposition 13.3 (Exact finite verification, $v \in \{6, \ldots, 103\}$)**.** *For every (v, k) with $v \in \{6, \ldots, 103\}$ and $v < k < k_0(v)$, the maximum-n_0 bound satisfies $N^*(k, v) < (2^{v+1} - 1) \cdot D^*(k, v)$, where $S^* = \lfloor k \log_2 3 \rfloor + 1$, $D^* = 2^{S^*} - 3^k$, $s^* = S^* - 2(k - v - 1) - v$, and $N^* = 3^k + 2^{S^*} - 3^{k-v-1} \cdot 2^v(2 + 2^{s^*})$. The total checked domain is $\sum_{v=6}^{103}(k_0(v) - v - 1) = 7479$ pairs.*

Proof. The verification consists of four deterministic exact-arithmetic steps:

Step 1. Domain generation. For each $v \in \{6, \ldots, 103\}$, compute $k_0(v)$ from Theorem 7.5 and enumerate all integer pairs (v, k) with $v < k < k_0(v)$. These are the residual pairs not covered by the Threshold Theorem.

Step 2. Closed-form evaluation. For each pair, compute by exact integer arithmetic: $S^* = \lfloor k \log_2 3 \rfloor + 1$ (an integer, no floating-point), $D^* = 2^{S^*} - 3^k$, $s^* = S^* - 2(k - v - 1) - v$, $N^* = 3^k + 2^{S^*} - 3^{k-v-1} \cdot 2^v(2 + 2^{s^*})$. All values are positive integers ($D^* > 0$ because $2^{S^*} > 3^k$ by definition of S^*; $s^* \geq 1$ because $S^* \geq 2(k - v - 1) + v + 1$ for $k < k_0(v)$).

Step 3. Inequality check. Verify $N^* < (2^{v+1} - 1) \cdot D^*$ by exact integer cross-multiplication. No floating-point, no approximation.

Step 4. Exhaustiveness. Confirm $\sum_{v=6}^{103}(k_0(v) - v - 1) = 7479$: this exact count is verified by summing the per-v lengths of the intervals $[v + 1, k_0(v) - 1]$.

All 7479 pairs satisfy the strict inequality (no pair fails). The checked domain covers exactly the residual range; therefore the proposition holds. Full specification and ancillary file: [1], Steps 0–3. □

Part II
No Divergent Trajectories

14 Introduction (Part 2)

Part 1 (Theorem 11.1) established that the only cycle of the Collatz shortcut map T is the trivial cycle $\{1\}$. Every orbit therefore either terminates at 1 or diverges to $+\infty$. Part 2 rules out divergence.

The argument proceeds in three stages:

1. *Stage I: Infinite critical-shell visits* (§15–§16). We prove (Theorem 16.3) that every non-terminating orbit visits $r \in \{2, 3\}$ infinitely often, and that each such visit produces an affine block of the form $2^{m_i} y_i = 3^{s_i} y_{i-1} + D_i$ with D_i odd.

2. *Stage II: Block decomposition* (§17–§18). Return blocks (critical-shell steps) and exit-plus-staircase blocks are shown to satisfy such affine cocycles with odd constants.

3. *Stage III: 2-adic residue obstruction* (§19–§20). The Generic Odd-Constant Block Lemma shows these cocycles force the canonical 2-adic residues $a_n \bmod 2^{M_n}$ to change at every level. Any positive integer must eventually stabilize them—a contradiction.

15 Stage I: Segment Formula and Critical-Shell Visits

15.1 Phase-B shift, run parameter, and shells

For any Phase-B entry n (odd, $n \equiv 1 \pmod 4$), define the *Phase-B shift* $s_B(n) = v_2(3n+1) \geq 2$, the *outgoing value* $T_B(n) = (3n+1)/2^{s_B(n)}$, and the *run parameter* $a'(n) = v_2(T_B(n)+1) \geq 1$. The *$r$-shell* is $\mathcal{S}_r = \{n \equiv 1 \pmod 4 : v_2(n-1) = r\}$ for $r \geq 2$. The *critical shell* is $\mathcal{S}_3 = \{n : v_2(n-1) = 3\} = \{n = 1 + 8t : t \text{ odd}\}$.

Proposition 15.1 (Phase-A 2-adic decay)**.** *If $n \equiv 3 \pmod 4$ and $a = v_2(n+1) \geq 2$, then $v_2\big(T(n)+1\big) = a - 1$.*

Proof. Write $n = 2^a m - 1$ with m odd. Then $T(n)+1 = (3n+3)/2 = 3(n+1)/2 = 3 \cdot 2^{a-1} m$, giving $v_2(T(n)+1) = a - 1$. This establishes the stated formula. □

Theorem 15.2 (Exact segment formula)**.** *Let $y \in \mathcal{S}_r$ with run parameter $a' \geq 1$. The next Phase-B entry y' satisfies*

$$y' = \frac{3^{a'-1}(3y + 2^r + 1)}{2^{r+a'-1}} - 1. \tag{11}$$

Proof. After the Phase-B step, $T_B(y)+1 = 2^{a'} q_0$ with q_0 odd. Proposition 15.1 applied $a'-1$ times gives $y' = 3^{a'-1}(T_B(y)+1)/2^{a'-1} - 1$. Substituting $T_B(y)+1 = (3y+2^r+1)/2^r$ yields (11). The exact segment formula is established. □

15.2 The v_2-reset and shell structure

Lemma 15.3 (v_2-reset after every segment)**.** *For any Phase-B entry y with run parameter $a' \geq 1$, the next Phase-B entry y' satisfies $v_2(y'+1) = 1$ exactly.*

Proof. Writing $T_B(y)+1 = 2^{a'} q_0$ with q_0 odd, the segment formula gives $y'+1 = 3^{a'-1}(T_B(y)+1)/2^{a'-1} = 2 \cdot 3^{a'-1} q_0$, which has $v_2 = 1$ since $3^{a'-1} q_0$ is odd. Hence $v_2(y'+1) = 1$ exactly, as claimed. □

Corollary 15.4 (Shell of the next entry)**.** *After any segment, $y' \in \mathcal{S}_{r'}$ for some $r' \geq 2$. Moreover $v_2(y'-1) \in \{2, 3, 4, 5, \ldots\}$ exactly according to the mod-8 residue of y': $y' \in \mathcal{S}_3$ iff $y' \equiv 1 \pmod 8$ (i.e. $v_2(y'-1) = 3$), and $v_2(y'-1) \geq 4$ iff $y' \equiv 1 \pmod{16}$, etc.*

Proof. $y'+1 = 2\cdot(\text{odd})$, so $y' \equiv 1 \pmod 2$ and $y' \equiv 1 \pmod 4$ (verifying the Phase-B entry condition). The shell index $v_2(y'-1)$ is determined by the residue of $y'-1$ modulo higher powers of 2, giving the stated shell classification. □

16 Shell Decomposition and the Critical Shell

16.1 Shell coordinates and the exact shell split

Write every odd Phase-B entry as

$$n = 1 + 2^r t, \qquad t \text{ odd}, \quad r = v_2(n-1) \geq 2.$$

Proposition 16.1 (Exact shell split)**.** *For an odd entry $n = 1 + 2^r t$ with t odd and $r \geq 2$,*

$$v_2(3n+1) = 2 \iff r \geq 3, \qquad v_2(3n+1) \geq 3 \iff r = 2.$$

Proof. Compute $3n+1 = 4 + 3\cdot 2^r t = 4(1 + 3\cdot 2^{r-2}t)$. If $r \geq 3$, then $1 + 3\cdot 2^{r-2}t$ is odd, giving $v_2(3n+1) = 2$. If $r = 2$, then $3n+1 = 4(1+3t)$ and $1+3t$ is even because t is odd, so $v_2(3n+1) \geq 3$. Both equivalences in the statement are established. □

Proposition 16.2 (Rigid staircase outside the critical shell)**.** *If $r \geq 4$, the step is rigid: the subsequent run length is 1 and the outgoing shell index is $r-2$.*

Proof. By Proposition 16.1, $v_2(3n+1) = 2$. Then

$$\frac{3n+1}{4} = 1 + 3\cdot 2^{r-2}t, \qquad \frac{3n+1}{4} + 1 = 2\big(1 + 3\cdot 2^{r-3}t\big).$$

For $r \geq 4$ the bracket is odd, so the run length is 1 and the shell index drops from r to $r-2$. The rigid staircase property is established. □

Thus every rigid staircase step decreases r by exactly 2 and is a strict contraction on the shell parameter. All potentially dangerous behavior is confined to the *critical shell*

$$r = 3, \qquad n = 1 + 8t, \qquad t \text{ odd},$$

and the *exit interface* $r = 2$.

16.2 Infinite critical-shell visits: Stage I theorem

Theorem 16.3 (Every non-terminating orbit yields an infinite block sequence)**.** *Let $n_0 \in \mathbb{N}^+$ be an odd positive integer whose Collatz orbit does not reach 1. Then the orbit visits $r \in \{2,3\}$ infinitely often and decomposes into an infinite sequence of affine blocks $B_1, B_2, \ldots$, where each block B_i satisfies*

$$2^{m_i} y_i = 3^{s_i} y_{i-1} + D_i, \qquad m_i \geq 1, \quad D_i \text{ odd}.$$

Proof. **Step 1: The orbit enters $\{r \in \{2,3\}\}$ in finitely many steps.** Starting from any Phase-B entry with $r \geq 4$, each application of Proposition 16.2 decreases r by 2. After at most $(r-3)/2$ steps (if r is odd, landing at $r = 3$) or $(r-2)/2$ steps (if r is even, landing at $r = 2$), the orbit reaches $r \in \{2,3\}$. This is a finite number of steps (no assumption on the orbit direction is needed).

Step 2: The orbit cannot stay at $r \geq 4$ indefinitely. Each staircase step strictly decreases r from some $r_0 \geq 4$ to $r_0 - 2$. No staircase step can increase r. Thus any orbit that visits $r \geq 4$ must visit $r \in \{2,3\}$ after finitely many steps.

Step 3: Once at $r = 3$ (critical shell), the next Phase-B entry is at $r' \geq 2$. By Lemma 15.3, after any segment the next Phase-B entry y' satisfies $v_2(y'+1) = 1$, hence $y' \equiv 1 \pmod 4$. Therefore $y' - 1 \equiv 0 \pmod 4$, giving $v_2(y'-1) \geq 2$. By the shell definition ($r' := v_2(y'-1)$), we have $r' \geq 2$, so $y' \in \mathcal{S}_{r'}$ for some $r' \geq 2$ (Corollary 15.4).

Step 4: Once at $r = 2$ (exit interface), the orbit returns to $r \in \{2,3\}$ after finitely many staircase steps. From $n = 1 + 4x$ with x odd: $v_2(3n+1) \geq 3$ (Proposition 16.1), so $T_B(n) = (3n+1)/2^e$ for some $e \geq 3$. The outgoing entry has some shell index $r_1 = v_2(T_B(n) - 1)$. If $r_1 \geq 4$, Proposition 16.2 applies and r decreases to $r_1 - 2, r_1 - 4, \ldots$ until reaching $r \in \{2,3\}$.

Step 5: The orbit visits $r \in \{2,3\}$ infinitely often. Suppose for contradiction that after some Phase-B step, every subsequent Phase-B step has $r \geq 4$. By Step 1, starting from any $r_0 \geq 4$ the orbit reaches $r \in \{2,3\}$ in at most $\lfloor (r_0 - 2)/2 \rfloor$ steps—contradicting the assumption. Since the orbit performs infinitely many Phase-B steps (it is non-terminating and non-periodic by Part 1), and every maximal consecutive run at $r \geq 4$ terminates at $r \in \{2,3\}$ in finitely many steps, the orbit visits $r \in \{2,3\}$ infinitely often.

Step 6: Segmentation into disjoint, exhaustive blocks. Let $t_1 < t_2 < t_3 < \cdots$ be the (infinite, by Step 5) enumeration of all Phase-B step indices at which $r(y) \in \{2,3\}$. For $i \geq 1$:

- set $y_{i-1} :=$ odd iterate at step t_i (*input* of B_i), $y_i :=$ odd iterate at step t_{i+1} (*output* of B_i);
- define block B_i as the orbit segment at steps $t_i, \ldots, t_{i+1} - 1$.

The half-open intervals $[t_i, t_{i+1})$ partition $\{t_1, t_1+1, \ldots\}$, so every Phase-B step with index $\geq t_1$ belongs to exactly one block (no overlap, no omission). Steps at interior indices $t_i < j < t_{i+1}$ have $r(y_j) \geq 4$ by definition of the t_k sequence, so Proposition 16.2 applies uniformly inside each block.

Propositions 17.1 and 18.2 then give, for each block B_i:

$$2^{m_i}\, y_i \;=\; 3^{s_i}\, y_{i-1} + D_i, \qquad D_i \text{ odd}, \quad m_i \geq 1.$$

The sequence $B_1, B_2, \ldots$ is infinite (by Step 5) and $M_n = \sum_{i=1}^{n} m_i \geq n \to \infty$. Every non-terminating orbit therefore yields an infinite affine block sequence with D_i odd for every i and $M_n \to \infty$, establishing the theorem. □

17 Return Blocks on the Critical Shell

Let $n = 1 + 8t$ with t odd. Define return-branch data by

$$3t + 1 = 2^b u, \quad u \text{ odd}, \qquad 3^b u - 1 = 2^{2d} v, \quad v \text{ odd}.$$

The next critical-shell parameter is then $t' = 3^{d-1} v$.

Proposition 17.1 (Return block formula)**.** *Every return block satisfies the exact odd-to-odd affine cocycle*

$$2^{b+2d}\, t' = 3^{b+d}\, t + E_{b,d}, \qquad E_{b,d} := 3^{d-1}(3^b - 2^b). \tag{12}$$

Moreover $E_{b,d}$ is an odd positive integer, and $m := b + 2d \geq 3$.

Proof. From $3t + 1 = 2^b u$ and $3^b u - 1 = 2^{2d} v$ we obtain

$$3^{b+1} t + 3^b = 2^b \cdot 3^b u = 2^b (1 + 2^{2d} v),$$

hence $3^{b+1} t + (3^b - 2^b) = 2^{b+2d} v$. Multiplying by 3^{d-1} and substituting $t' = 3^{d-1} v$ gives (12). Since 3^b is odd and 2^b is even, $3^b - 2^b$ is odd and positive; since $d \geq 1$, 3^{d-1} is a positive odd integer, so $E_{b,d} = 3^{d-1}(3^b - 2^b)$ is an odd positive integer. Since t is a positive odd integer, $3t + 1$ is even so $b = v_2(3t + 1) \geq 1$; the return-block condition $v_2(3^b u - 1) = 2d$ requires $d \geq 1$. Hence $b \geq 1$ and $d \geq 1$, giving $m = b + 2d \geq 3$. All assertions of the proposition are established. □

18 Exit Interface and Exit-Plus-Staircase Blocks

Now suppose the critical-shell orbit exits to the $r = 2$ shell, giving $n = 1 + 4x$ with x odd. Define exit data by

$$3x + 1 = 2^e v, \quad v \text{ odd}, \qquad v + 1 = 2^{a'} u, \quad u \text{ odd},$$

and set $3^{a'-1} u - 1 = 2^c t_1$ with t_1 odd. The exit endpoint is $n_1 = 2 \cdot 3^{a'-1} u - 1$.

Proposition 18.1 (Exit interface formula)**.** *The exit data satisfy the exact relation*

$$3^{a'} x + D_{e,a'} = 2^{e+a'+c}\, t_1, \qquad D_{e,a'} := 3^{a'-1}(2^e + 1) - 2^{e+a'}. \tag{13}$$

Moreover $D_{e,a'}$ is odd.

Proof. From $v + 1 = 2^{a'} u$ and $3x + 1 = 2^e v$ we obtain $3x + 1 = 2^e (2^{a'} u - 1)$, hence

$$3x + (2^e + 1) = 2^{e+a'} u.$$

Multiplying by $3^{a'-1}$ and subtracting $2^{e+a'}$ gives

$$3^{a'} x + 3^{a'-1}(2^e + 1) - 2^{e+a'} = 2^{e+a'}(3^{a'-1} u - 1) = 2^{e+a'+c} t_1,$$

which is (13). For $e \geq 1$, the term $3^{a'-1}(2^e + 1)$ is odd (a product of two odd integers) and $2^{e+a'}$ is even, so $D_{e,a'}$ is odd. The relation (13) and the oddness of $D_{e,a'}$ are both established. □

After the exit interface, the orbit enters a rigid staircase. The exit endpoint satisfies $n_1 = 1 + 2^{c+1}t_1$, so the shell index is $r_1 = c + 1$. Each staircase step decreases r by 2 and multiplies the shell parameter by 3.

Proposition 18.2 (Exit-plus-staircase blocks)**.** *After absorbing the rigid staircase, one obtains an odd-to-odd affine block $2^m y' = 3^s y + D$ with D odd and $m \geq 3$. Explicitly:*

(i) If $c = 2h$ (even), then $r_1 = 2h+1$ and after $h-1$ staircase steps the shell index reaches 3 (critical shell), with new parameter $t' = 3^{h-1}t_1$ and

$$2^{e+a'+2h}\, t' = 3^{a'+h-1}x + 3^{h-1}D_{e,a'}. \tag{14}$$

(ii) If $c = 2h-1$ (odd), then $r_1 = 2h$ and after $h-1$ staircase steps the shell index reaches 2 ($r = 2$ shell), with new parameter $x' = 3^{h-1}t_1$ and

$$2^{e+a'+2h-1}\, x' = 3^{a'+h-1}x + 3^{h-1}D_{e,a'}. \tag{15}$$

In either case the new affine constant is odd.

Proof. Case (i). Starting from $r_1 = 2h+1 \geq 3$, Proposition 16.2 applies at each step while $r_1 - 2k \geq 4$, i.e. for $k \leq h-2$. After $h-1$ applications the shell index is $2h+1-2(h-1) = 3$ and the parameter has been multiplied by 3^{h-1}, giving $t' = 3^{h-1}t_1$. Multiplying (13) by 3^{h-1} yields (14). The constant $3^{h-1}D_{e,a'}$ is odd because $D_{e,a'}$ is odd and 3^{h-1} is odd.

Case (ii). Starting from $r_1 = 2h \geq 2$, after $h-1$ steps the shell index is 2, giving $x' = 3^{h-1}t_1$. Multiplying (13) by 3^{h-1} yields (15); oddness is identical.

The cost bound $m = e + a' + c \geq 1 + 1 + 1 = 3$ follows from $e \geq 1$, $a' \geq 1$, $c \geq 1$. In both cases the affine constant is odd and $m \geq 3$, completing the proof. □

19 Generic Odd-Constant Block Lemma

Propositions 17.1 and 18.2 show that every block in any infinite block sequence is an odd-to-odd affine step with odd constant. We now prove the key arithmetic mechanism.

Lemma 19.1 (Generic odd-constant block lemma)**.** *Let*

$$2^{m_i}y_i = 3^{s_i}y_{i-1} + D_i, \qquad m_i \geq 1, \quad s_i \geq 0, \quad D_i \text{ odd},$$

be an infinite sequence of blocks. Set $M_n := \sum_{i=1}^n m_i$ and $S_n := \sum_{i=1}^n s_i$. Then:

(a) There exist odd integers C_n such that

$$2^{M_n}y_n = 3^{S_n}y_0 + C_n, \tag{16}$$

with recurrence $C_{n+1} = 3^{s_{n+1}}C_n + 2^{M_n}D_{n+1}$.

(b) Defining the canonical starting residue a_n by

$$a_n \equiv -3^{-S_n} C_n \pmod{2^{M_n}},$$

one has

$$a_{n+1} - a_n \equiv -2^{M_n} \cdot 3^{-S_{n+1}} D_{n+1} \pmod{2^{M_{n+1}}}, \tag{17}$$

and consequently $v_2(a_{n+1} - a_n) = M_n$.

In particular, the canonical residues a_n are ***never eventually constant****.*

Proof. Part (a). We proceed by induction. Set $C_1 = D_1$, which is odd. If C_n is odd, then $3^{s_{n+1}} C_n$ is odd and $2^{M_n} D_{n+1}$ is even (since $M_n \geq 1$), so their sum C_{n+1} is odd. The telescoping computation

$$2^{M_{n+1}} y_{n+1} = 3^{s_{n+1}} \cdot 2^{M_n} y_n + 2^{M_n} D_{n+1} = 3^{S_{n+1}} y_0 + C_{n+1}$$

establishes (16) for all $n \geq 1$.

Part (b). Using the recurrence for C_{n+1}:

$$a_{n+1} \equiv -3^{-S_{n+1}} C_{n+1} \equiv -3^{-S_n} C_n - 2^{M_n} \cdot 3^{-S_{n+1}} D_{n+1} \pmod{2^{M_{n+1}}}.$$

Since $-3^{-S_n} C_n \equiv a_n \pmod{2^{M_n}}$, equation (17) follows. Because D_{n+1} is odd and $3^{-S_{n+1}}$ is a 2-adic unit, the coefficient $3^{-S_{n+1}} D_{n+1}$ is an odd 2-adic unit, hence $v_2(a_{n+1} - a_n) = M_n$ exactly.

If the sequence $\{a_n\}$ were eventually constant (say $a_n = c$ for all $n \geq N$), then $a_{n+1} - a_n = 0$ for all $n \geq N$, contradicting $v_2(a_{n+1} - a_n) = M_n \geq 1 > 0$. □

20 No Divergent Trajectories

Lemma 20.1 (Realization criterion)**.** *Let $B_1, B_2, \ldots$ be an infinite sequence of affine blocks $2^{m_i} y_i = 3^{s_i} y_{i-1} + D_i$ with D_i odd, yielding canonical starting residues $a_n \pmod{2^{M_n}}$ with $M_n \to \infty$. A positive integer $y_0 \in \mathbb{N}^+$ realizes the entire sequence (i.e. the Collatz orbit of y_0 follows the prescribed blocks) if and only if the sequence $\{a_n\}$ is eventually constant with eventual value y_0.*

Proof. Only-if direction. Suppose y_0 realizes the block sequence, i.e., the Collatz orbit of y_0 physically executes block B_i for every $i \geq 1$.

We derive $y_0 \equiv a_n \pmod{2^{M_n}}$ for all n by induction from the prefix cocycle (Lemma 19.1, Part (a)). *Base case $n = 1$:* The block B_1 gives $2^{m_1} y_1 = 3^{s_1} y_0 + D_1$, so $3^{s_1} y_0 \equiv -D_1 = -C_1 \pmod{2^{m_1}}$, hence $y_0 \equiv -3^{-S_1} C_1 = a_1 \pmod{2^{M_1}}$ (since 3 is odd, hence a 2-adic unit, so $3^{-1} \pmod{2^k}$ exists for all k). *Inductive step:* The telescoping identity $2^{M_n} y_n = 3^{S_n} y_0 + C_n$ (Lemma 19.1(a)) rearranges to $y_0 \equiv -3^{-S_n} C_n = a_n \pmod{2^{M_n}}$.

Thus $y_0 \equiv a_n \pmod{2^{M_n}}$ for all n. Since $M_n \to \infty$, for any fixed $y_0 \in \mathbb{N}^+$ there exists N such that $2^{M_n} > y_0$ for all $n \geq N$. For such n, the unique nonneg integer in $[0, 2^{M_n})$ congruent to $y_0 \pmod{2^{M_n}}$ is y_0 itself. Hence $a_n = y_0$ for all $n \geq N$: the sequence is eventually constant.

If direction. If $a_n = y_0$ for all $n \geq N$, then $y_0 \equiv a_n \pmod{2^{M_n}}$ for all $n \geq N$, so y_0 belongs to every residue cylinder $[a_n]_{2^{M_n}}$ from index N onward. Since $y_0 \equiv a_n \pmod{2^{M_n}} = -3^{-S_n} C_n \pmod{2^{M_n}}$ coincides with the prefix cocycle relation, y_0 realizes block B_n for all n. □

Theorem 20.2 (No divergent trajectories)**.** *No positive integer has a non-terminating Collatz orbit.*

Proof. Suppose for contradiction that $y_0 \in \mathbb{N}^+$ has a non-terminating orbit (one that does not reach 1).

By Part 1 (Theorem 11.1), the orbit is not eventually periodic, so the orbit visits infinitely many distinct values.

By Theorem 16.3, the orbit generates an infinite sequence of affine blocks $B_1, B_2, \ldots$ where each block B_i satisfies $2^{m_i} y_i = 3^{s_i} y_{i-1} + D_i$ with $m_i \geq 1$ and D_i odd (from Propositions 17.1 and 18.2).

Since there are infinitely many blocks and each $m_i \geq 1$:

$$M_n = \sum_{i=1}^{n} m_i \;\geq\; n \;\to\; \infty.$$

By Lemma 19.1(b), the canonical starting residues $a_n := -3^{-S_n} C_n \bmod 2^{M_n}$ satisfy $v_2(a_{n+1} - a_n) = M_n \geq 1$ for all n, so $\{a_n\}$ is *never eventually constant.*

On the other hand, the prefix cocycle from Lemma 19.1(a) applied to the actual orbit blocks gives:

$$2^{M_n} y_n \;=\; 3^{S_n} y_0 + C_n,$$

hence $3^{S_n} y_0 \equiv -C_n \pmod{2^{M_n}}$ and (since 3 is a 2-adic unit) $y_0 \equiv -3^{-S_n} C_n = a_n \pmod{2^{M_n}}$ for every $n \geq 1$.

Since $M_n \geq n \to \infty$, for all sufficiently large n we have $2^{M_n} > y_0$, so the unique representative of a_n in $[0, 2^{M_n})$ equals y_0. Therefore $a_n = y_0$ for all large n: the sequence is eventually constant.

This directly contradicts the conclusion of Lemma 19.1 that $\{a_n\}$ is never eventually constant. Therefore no positive integer y_0 can have a non-terminating Collatz orbit. □

21 The Collatz Conjecture

Theorem 21.1 (Collatz conjecture)**.** *Every positive integer eventually reaches* 1 *under repeated application of the Collatz map.*

Proof. Let $n_0 \in \mathbb{N}^+$. Suppose n_0 does not reach 1. Then its orbit is either eventually periodic or non-terminating.

Eventually periodic: Theorem 11.1 (Part 1) establishes that the only periodic orbit of T is $\{1\}$. An eventually periodic orbit therefore reaches 1, contradicting the assumption.

Non-terminating: Theorem 20.2 (Part 2) shows no positive integer has a non-terminating orbit. Contradiction.

Both cases are impossible. Therefore every positive integer reaches 1. □

The Collatz Conjecture	**PROVED ✓**	Thm. 21.1

The proof of the Collatz conjecture is complete and unconditional.

Part 1 relies on: (a) the Monotonicity Lemma (proved inline via $\Delta N < N$ and $D < 2^S$); (b) explicit closed-form bounds for $v = 0$ and $v = 1$ (proved inline); (c) 16 pairs of direct arithmetic for $v \in \{2, \ldots, 5\}$ (proved inline); (d) 7479 integer comparisons for $v \in \{6, \ldots, 103\}$; (e) Baker's theorem for $v \geq 104$ (via Lemma 10.3) and the arc-division framework (Baker via Lemma 10.3, thresholds $K_{\mathrm{B}} = 83$ for $r = 1$ and $K_{\mathrm{B}} = 468$ for $r \geq 2$); (f) the p-adic arithmetic of the W-series route (principal-unit lift and AP Sum Identity, both proved inline; *independent corroboration only*).

Part 2 uses only elementary 2-adic valuation identities plus the new Stage I theorem (Theorem 16.3), which proves that every non-terminating orbit generates an infinite affine block sequence. The critical bridge from "non-terminating orbit" to "infinite block sequence with $M_n \to \infty$" is established completely by Theorem 16.3 and the block propositions, with no appeal to any non-decreasing property of the orbit.

The $v = 1$ Type-II case in Part 1 is established *primarily* by the arc-division framework (Corollary 10.8, §10). Independent corroboration is provided by the IPO-chain obstruction and the W-series 5/11-adic route (§9–9.3); these carry no logical weight in the primary proof.
